Abstract There are a large number of drugs inducing headache as an adverse reaction. Nevertheless, headaches as adverse reactions to drugs have received limited attention. Non-serious adverse reactions, such as headache, are not quantified and described as accurately as serious, life threatening ones. However, non-serious reactions can also be extremely troublesome, above all when they are chronic: they can affect patients' quality of life and contribute to non-compliance. It is absolutely possible that the number of patients with headache as an adverse reaction, which is going to increase, considering the growing use of medications. Physicians should, therefore, be aware of this issue. Indeed, it is difficult to attribute the diagnosis of adverse drug reaction to a condition, headache, which is also a very common symptom in general population.

Keywords Adverse drug reaction · Classification · Pharmacovigilance · Headache · Migraine · Side effect

Introduction

Headaches as adverse reactions to drugs have not been much studied both in the field of pharmacovigilance, and by headache clinicians and researchers, even if a very large number of drugs, with different mechanisms of action, can induce headache in acute or chronic treatment or after drug discontinuation [1]. The aims of this paper are (1)

underscoring the lack of information on headache as an adverse reaction, and (2) stimulate to recognize the kind of adverse reaction headache, in order to properly treat it.

Adverse reactions

Medications are classified according to their main therapeutic action, but no drug induces only one specific effect. Drugs can be selective, but they are rarely specific. They induce two kinds of effects: those useful for treatment and those non-relevant to this aim and unintended. The latter are defined “side effects” or, more specifically, adverse reactions. An adverse drug reaction (ADR) is a response to a drug that is noxious and unintended and occurs at doses normally used in people for the prophylaxis, diagnosis or therapy for the disease, or for modification of physiological function [2]. Adverse reactions are classified into serious and non-serious or low-risk reactions. A serious reaction is one that results in death, requires hospital admission or prolongation of existing hospital stay, results in persistent or significant disability/incapacity, or is life threatening [3].

Adverse reactions are categorized into five types, the most important of which are type-A (augmented), dose-dependent, and type-B (bizarre), non-dose-dependent [4]. Most adverse reactions, approximately 75% [5], belong to type-A [6]. These ADRs are relatively easy to diagnose, since they can be predicted according to the main action of the drug and are, therefore, generally identified in the study preceding the marketing of the drug. They have high morbidity, but are practically never life threatening. Furthermore, they can disappear if drug dosage is reduced [6]. Type-B reactions are also termed idiosyncratic, owing to their unpredictable nature and our lack of understanding of the mechanisms involved. There is no dose-response

relationship, incidence is very low (<1/1,000), but they are often serious and potentially life threatening. They are often not detected until the drug has been released onto the market and they are sometimes detected even after years of use. Type-B reactions, therefore, represent a major clinical problem [7]. Type-C reactions (arising from chronic use) are induced by the long-term effect of the drug and its metabolites: for example, the long-term toxicity of amiodarone. Type-D (delayed) is adverse reactions that appear later and are more serious than type-C: for example, bladder cancer in patients who had been treated for a long period with cyclophosphamide. Type-E reactions (end of treatment) arise from discontinuing treatment [8].

The identification of ADRs has remarkably improved in the last decades [9]. Nevertheless, reactions that are not life threatening are not systematically studied and quantified with the same accuracy as those which are considered serious [10]. Serious events are five times more likely to be reported than non-serious ones [11, 12]. Even when they are reported, non-serious ADRs are often not described in detail, unless the event is a study endpoint or it is of particular interest. This is unfortunate, because non-serious ADRs can be very worrying [13], above all when they are chronic: they can affect patients' quality of life, reduce adherence to treatment or cause drug discontinuation [10, 14, 15].

There are various information sources about ADRs. The most important ones are randomized controlled trials, epidemiological post-marketing studies, and spontaneous reporting [16]. ADR headache is very frequent, whatever the source is. However, information about this ADR is usually limited and does not allow a precise assessment. Clinical trials should, therefore, be able to determine ADR headache more accurately; above all, when the drug studied is related to a previously marketed compound able to induce headache, or its mechanism of action can supposedly cause headache. Moreover, when the results of clinical trials are published, the proportion of patients that discontinued drug treatment as a consequence of headache should also be reported together with a detailed description of the characteristics of the symptom and of the patients.

The actual frequency of an ADR headache is only known when a drug has been studied both in patients taking

it and in placebo group. The importance of this datum is also stressed in ICHD-II [17], which specifies in chapter 8.1 that “only when headache occurs more often after active drug than after placebo in double blind trials it can be regarded as true effect”. Nevertheless, the placebo effect can substantially vary across trials with the same drug [18]. The frequency of ADR headache can also be influenced by the presence of headache sufferers, who could be much more susceptible to this adverse reaction than non-headache subjects [17]. Patients should therefore be screened to detect headache before clinical trial enrolment and headache sufferers should be separately assessed.

ADR headache

ICDH-II [17] includes secondary headaches attributed to drugs or their withdrawal, which can be fully considered adverse reactions to drugs, in chapter 8, codes 8.1, 8.3, and 8.4. Many other ADR headaches have also been less studied and characterized that in lacking elements for a more accurate description, ICHD-II itself [17] only gives a list of the drugs, which can induce them in the appendix.

The two mechanisms inducing headache as an adverse reaction have been classically considered: one is vasodilatation and the other is raised intracranial pressure. Vasodilatation explains headache induced by most cardiovascular drugs such as calcium-channel blockers and ACE inhibitors. In these cases, headache is a side effect related to the primary pharmacological action of the drug, it is often dose-dependent, but it already appears with the dosages normally used in therapy. Headache related to aseptic meningitis induced by drugs is instead a type-B adverse reaction, not predictable from the mechanism of action of the medication that induces it [1].

Many ADR headaches can have the characteristics of migraine, tension-type headache or cluster headache (Table 1) and could therefore contribute to the high individual and social cost of these diseases. The burden associated with primary headache is a major public health problem [19]. In a retrospective study carried out in the Netherlands [20], headache was the third ADR most frequently reported by patients and even the first reported by

Table 1 Characteristics of headaches attributed to drugs and drug classes

Characteristic	Drug
Migraine without aura	Cyclosporin [31], Dipyridamole [32], Nitric oxide donors [33], Phosphodiesterase inhibitors [34], Interferon- β [35], Ondansetron [36], Tacrolimus [37], Sertraline [38]
Migraine with aura	Nitric oxide donors [39], Phosphodiesterase inhibitors [34], Tacrolimus [40], Fluoxetine [41]
Typical aura without headache	Tadalafil [42]
Cluster headache	Nitric oxide donors [43], Phosphodiesterase inhibitors [44]

health-care professionals in the year 2004–2007. Patients only report reactions which they consider important; they do not instead report the ones which they consider non-serious, unless they are specifically questioned (which has not been done in this study). These results therefore indicate that, even if it was considered non-serious, headache was very important, both for patients and for health-care professionals. There are no standardized and universal rating scales to categorize the severity of ADR. There is no single risk–benefit evaluation for a drug; it is context-dependent [21]. For example, the risk of headache induced by an immunosuppressant treatment is less important than the benefit, whereas it becomes more relevant in cases that only require anti-acid therapy.

Considering the growing number of people taking drugs [22], headache clinicians are likely to treat patients with polymedication and headaches as ADRs, difficult to diagnose and manage. In this context, every time a patient reports the onset of a headache he had never suffered from or the worsening of or change in the headache he has been suffering from for a long time, the physician shall also take into consideration, in differential diagnosis, that this headache can be an adverse reaction to a drug. An accurate pharmacological anamnesis is fundamental in order to diagnose headache as an adverse reaction. Nevertheless, it can be very difficult to attribute the diagnosis of ADR to a condition such as headache, which is also a common symptom, not pathognomonic of any pathological condition, and extremely widespread among general population (the percentage of the adult population with an active

headache disorder is 47% for headache in general) [23]. Primary headaches, such as ADRs, are prevalent in females [24]. In clinical practice, the consequences of this fact are probably reduced because episodic primary headaches mainly affect young adults who take few medications [23]. However, a large number of chronic headache patients attend a tertiary clinic and the majority of them are elderly women with multiple co-morbid conditions and polypharmacy [24, 25], and therefore are at a higher risk of ADRs [26].

In order to define the causal relationship between drug and adverse reaction, the time elapsed between the onset of headache and the administration of the drug must be considered and it must be assessed if the headache is compatible with the well-known pharmacological properties of the substance. However, the best proofs of the causal relationship are the disappearing of headache after discontinuing the drug and its onset when the patient takes the medication again [27].

Failing to detect ADR headache can cause patients' suffering, anxiety, worrying, and a high social cost: diagnostic tests, other physicians' consultations, and prescription of more drugs, while the solution is exactly the opposite, i.e., to reduce the number of drugs [28].

Researchers should also be interested in ADR headache, considering the fundamental role that drugs have had and will have in deepening the knowledge of pathogenetic mechanisms of primary headaches. An example is NO donors. These drugs have been widely used in experimental models and diagnostic tests to study headaches [29].

Table 2 Classification of ADR headaches according to the type of adverse reaction (drug-induced headaches reported in ICHD-II have not been included when there are no elements proving or suggesting the causal link between drug and headache)

Headache type	Drugs implied
1. Headache as type-A adverse drug reaction: predictable, related to the principal pharmacological action of the drugs, and dose-dependent	Nitric oxide (NO) donors (code 8.1.1), Phosphodiesterase (PDE) inhibitors (code 8.1.2), Calcitonin gene-related peptide-CGRP (code 8.1.9), Cocaine (code 8.1.6), Ethanol (code 8.1.4), Cannabis (code 8.1.7), Histamine (code 8.1.8), Calcium-channel blockers (Table 1 in the appendix), Antiarrhythmics, β -Adrenergic blockers, Ace inhibitors, Sympathomimetics (code 10.3.6), Antagonists of the at-1 receptors for Angiotensin II, Statins, α_2 -Adrenergic agonist (Clonidine), α_1 -Adrenergic blockers (Doxazosin and Prazosin), Amiloride, Methylxanthines, β_2 -Adrenergic agonists, Agents for erectile dysfunction, Ergotamine (Table 1 in the appendix), Nicotine (code 8.1.10), Amphetamine (code 10.3.6)
2. Headache as type-B adverse drug reaction: idiosyncratic, unpredictable, and related to aseptic meningitis (code 7.3.2)	Amoxicillin, Carbamazepine, Diclofenac, Famotidine, Ibuprofen, Immune globulin, Infliximab, Ketorolac, Leflunomide, Levamisole, Metronidazole, Naproxen, Ranitidine, Rofecoxib, Sulfamethoxazole, Sulfasalazine, Sulindac, Tolmetin, Trimethoprim, Valacyclovir
3. Headache as type-C adverse drug reaction: after chronic medication, related to raised intracranial pressure (code 8.3 and code 7.1.2)	Amiodarone, Anabolic steroids, Contraceptives Combination, Ciprofloxacin, Danazol, Corticosteroids, Gentamicin, Lithium Carbonate, Nalidixic Acid, Nitrofurantoin, Ofloxacin, Retinoic Acid, Tetracycline, Thyroid hormone replacement, Vitamin A
4. Headache as type-E adverse drug reaction: related to substance withdrawal	Caffeine-withdrawal headache (code 8.4.1), Opioid-withdrawal headache (code 8.4.2), estrogen-withdrawal headache (code 8.4.3), Ergotamine-withdrawal headache, Cocaine-withdrawal headache, Methysergide-withdrawal headache

* The codes reported in ICHD-II are in brackets

In order to give more elements to recognize and treat adverse reaction headaches, drug-induced headaches [excluding medication-overuse headache (code 8.2)] included in chapter 8 of the International Classification of Headache Disorders (ICHD-II) could also be classified according to the criteria and terminology used to categorize adverse reactions in the field of pharmacovigilance (Table 2). This classification stresses the pathophysiological basis of these “headaches induced by drug use”, an essential element to classify them as secondary. Furthermore, it suggests immediately the possible management of type-A adverse reaction headaches, that is to say, the reduction of drug dosage. This classification has some limitations, due to the uncertainty inherent in the different sources. However, we excluded drugs inducing percentages of headache lower than those induced by placebo. It should also be stressed in Table 2 that ADR headaches which clearly show the causal link between drug and headache are those classified into A and E types. The hypothesis of causal relationship is often only formulated considering the evolution of case reports in type-C headaches.

Classifications are very important to organize and manage knowledge and establish relationships between the various pieces of information. The classification of the International Headache Society has become a diffused standard in World wide communications between researchers and clinicians. The methods used to analyze and assess drug safety are more and more precise [30]. In this context, we also propose that clinical trials also assess if the side effect headache has or has not characteristics resembling migraine, tension-type headache or cluster headache. This effort should allow accurate descriptions of the headache’s characteristics before drug approval and it should make the diagnosis of ADR headache easier in clinical practice after the drug is marketed.

We hope that the sharing of the classification used in the field of pharmaco-vigilance and headaches will improve the management of patients’ problems.

Conflict of interest None.
